Technical Note

Mini-open Subpectoral Biceps Tenodesis Using All-Suture Anchor

Abbott Gifford, Tracy Tauro, B.S., B.A., Eric Haunschild, B.S., Kelechi Okoroha, M.D., and Brian J. Cole, M.D., M.B.A.

Abstract: The proximal biceps tendon is a common source of shoulder pain and dysfunction. When patients continue to have pain after exhaustive nonoperative treatment, the long head of the biceps tendon can be effectively treated with a tenotomy or tenodesis. Although biceps tenotomy is a less complex and highly reliable treatment, there is the potential for suboptimal outcomes including muscle cramping, fatigue, cosmetic deformity, and supination weakness. Biceps tenodesis eliminates the source of shoulder pain while securing the tendon proximally. Currently, there are multiple techniques for performing a biceps tenodesis (arthroscopic, open supraperceptoral, open subpectoral) and myriad fixation methods (biotenodesis screw, bone bridge, cortical button, all-suture anchor). Our article presents a technique for a mini-open subpectoral biceps tenodesis using an onlay technique with an all-suture anchor preloaded with needles. This technique allows efficient and proper tendon fixation while minimizing potential complications.

Pathology of the shoulder relating to the long head of the biceps (LHB) tendon can indicate a variety of different surgical treatments ranging from debridement to tenotomy and tenodesis depending on the specific patient characteristics. These surgical procedures are a viable next step for patients in whom all nonoperative management options have been exhausted and who have conditions including partial tearing of the biceps, biceps instability, subscapularis tendon tears, tenosynovitis, high-grade SLAP tears, and positive clinical examination findings for LHB pain.1 Surgery may also be indicated for patients who have specific rotator cuff pathologies and glenohumeral degenerative joint disease.2 The senior author (XXX) typically terminally indicates patients for biceps treatment after a reduction in symptoms immediately after an ultrasound-guided injection that includes local anesthetic.

Although some literature supports biceps tenotomy over tenodesis as a less complicated and more...
reliable procedure, tenotomy may lead to a Popeye deformity and loss of supination strength. More recent articles have shown that tenodesis provides better cosmesis, endurance, and strength outcomes in comparison to simple tenotomy and yields extremely low revision rates. For these reasons, in our practice, tenotomy is reserved for patients who are at elevated risk of infection or for whom these factors are not relevant. In addition, tenodesis is especially indicated in younger athletes, with two-thirds of the population able to return to sport after surgery. Biceps tenodesis can be performed using a variety of techniques including an arthroscopic versus open approach, proximal versus distal attachment, and numerous methods of suture fixation. We prefer a mini-open subpectoral biceps tenodesis because the literature and our experience suggest this procedure is accompanied by minimal residual pain and stiffness, as well as reliable clinical outcomes and a low complication rate. We present the primary method of biceps tenodesis of the senior author (XXX) using a mini-open subpectoral onlay technique with a double-loaded all-suture anchor (Biceps FiberTak; Arthrex, Naples, FL) loaded with broad 1.3-mm suture tape and swedged-on needles that prevent slippage while allowing the anchor to enter a small-diameter (1.9-mm) drill hole, which minimizes the risk of postoperative complications including fracture.

Positioning and Preparation
Before surgery, the patient is given an interscalene nerve block and placed under conscious sedation. An examination under anesthesia is performed to assess

Fig 2. Intraoperative image of the left shoulder with the patient in the beach-chair position and the arm abducted 20° to 30°. The soft tissue is dissected, an Army-Navy retractor is placed laterally for exposure, and a Chandler retractor is placed medially adjacent to the humerus under minimal tension. A pointed Hohmann retractor is placed over the top, underneath the deltoid and pectoralis major junction.

Fig 3. Intraoperative image of the left shoulder with the patient in the beach-chair position and the arm abducted 20° to 30°. An Army-Navy retractor is placed laterally for exposure; a Chandler retractor is placed medially adjacent to the humerus under minimal tension; and a pointed Hohmann retractor is placed over the top, underneath the deltoid and pectoralis major junction. (A) After the biceps is located by use of finger palpation on the anterior aspect of the humerus, the biceps tendon is isolated using a curved hemostat. (B) The previously arthroscopically released biceps tendon is retrieved from the proximal aspect of the joint and secured with a hemostat.
Surgical Technique

A standard diagnostic arthroscopy is performed to evaluate the glenoid, humeral head, labrum, rotator cuff, and biceps tendon for possible pathology. The biceps is examined and pulled into the joint with a probe to inspect along the length of the tendon. Any erythema, fraying, or partial tears are correlated with the patient’s symptoms, and a decision is made on treatment of the biceps. The stability of the biceps is also assessed as it relates to the upper border of the subscapularis tendon and the rotator interval—biceps sling. After the surgeon decides to proceed with the biceps tenodesis, an arthroscopic basket is introduced from the anterior portal while viewing from the posterior portal. The LHB is then incised at its attachment to the superior labrum with the basket (Video 1). An arthroscopic shaver (Torpedo; Arthrex) is used as needed to remove any residual biceps tendon. Before the biceps is secured with a mini-open approach, any additional pathology relating to the shoulder, such as rotator cuff or labral tears, is addressed.

To perform the tenodesis portion of the procedure, the head of the bed is reclined an additional 20° to 30°. The arm is slightly supinated and abducted. A marking pen is used to mark the longitudinal incision just lateral to the axillary crease, and local anesthesia is administered at the incision site (Fig 1, Video 1). A small (3-cm) longitudinal incision is made just beneath the inferior border of the pectoralis major and just medial to the anterior-medial border of the deltoid but lateral to the axillary crease (Video 1). The subcutaneous tissue and fascial layer are exposed using Metzenbaum scissors, and the fascia is entered inferior to the pectoralis major and lateral to the short head of the biceps (Video 1). A subpectoral plane is then established in the direction of the humerus via blunt finger dissection, and the LHB tendon can be palpated in the bicipital groove adjacent to the pectoralis major tendon edge (Video 1). The LHB tendon is better visualized by placing a small pointed Hohmann retractor under the junction of the pectoralis major and anterior-lateral border of the deltoid (Fig 2, Video 1). A Chandler retractor can be carefully placed on the medial aspect of the humerus; the neurovascular
structures that lie medially should be avoided (Fig 2, Video 1). The relative position of the muscle-tendon junction along the length of the humerus and distal biceps groove is identified and marked using electrocautery to best re-establish normal tension after tenodesis. The previously released LHB tendon is then retrieved using a finger or curved hemostat (Fig 3, Video 1).

Electrocautery is used to decorticate a 1.5 × 1.5–cm area in the subpectoral region at the proximal aspect of the exposure (Fig 4A, Video 1). An arthroscopic bone cutter is also used to decorticate the bone (Fig 4B, Video 1). The area of the humeral cortex to which the remaining LHB tendon is to be attached is "fish scaled" using the drill guide or osteotome and mallet (Fig 4C, Video 1). This process stimulates bony bleeding, which augments healing and prevents the tendon from migrating once attached. By use of a straight, slotted drill guide placed in the desired location of the proximal bicipital groove, a 1.9-mm hole is drilled (Fig 5A, Video 1). With the position of the drill guide being maintained, a double-loaded all-suture anchor (Biceps FiberTak) is carefully impacted into the drill hole (Fig 5B, Video 1). Once anchor fixation is established, 1 suture from each pair is passed through the LHB tendon with running, reinforced sutures over a 2-cm length of the tendon (Fig 5C, Video 1). The location chosen for the sutures is generally 1 cm from the musculotendinous junction to re-create normal tendon tension. The opposite ends of the paired sutures that were not passed are then used to tension and position the biceps tendon onto the humerus (Fig 6, Video 1). The wounds are then closed in a standard staged subcutaneous and subcuticular fashion using Monocryl suture (Ethicon, Somerville, NJ) and Dermabond (Ethicon) (Video 1).
**Fig 6.** Intraoperative image of the left shoulder with the patient in the beach-chair position and the arm abducted 20° to 30°. Army-Navy retractor is placed anteriorly and distally for exposure; a Chandler retractor is placed medially adjacent to the humerus under minimal tension; and a pointed Hohmann retractor is placed over the top, underneath the deltoid and pectoralis major junction. The unpassed suture ends are then used as a post to secure the biceps tendon onto the humerus, and the sutures are tied over the tendon, securing it in place. The remaining biceps is trimmed.

**Postoperative Management**

After the procedure, an ice pack is placed over the shoulder and an upper-extremity immobilizer is fitted to patients. Patients are instructed to wear the upper-extremity immobilizer for the first 2 weeks after surgery at all times except when performing instructed exercises or attending to personal hygiene. They are also advised to ice their shoulders for 20 minutes every 2 hours until their first postoperative visit (8-10 days). After their first visit, patients may begin hand and wrist range of motion and shoulder pendulum exercises no more than 2 or 3 times a day. They may not perform any more than active-assisted elbow flexion or supination exercises for 6 weeks after surgery.

Organized physical therapy begins 2 weeks after surgery. For the first 4 weeks after surgery, patients are instructed to only engage in passive range-of-motion exercises with their upper extremity. After this period, they begin isometric exercises of the deltoid and rotator cuff as tolerated. All exercises involving the biceps are avoided until at least 6 weeks after surgery, when isometric exercises are slowly introduced. By 8 weeks, eccentric resisted exercises of the biceps are initiated as tolerated. At 12 to 16 weeks postoperatively, patients are allowed to return to all previous activities.

**Discussion**

This article provides a simple and efficient technique for a mini-open subpectoral biceps tenodesis using an all-suture anchor with preloaded needles and suture tape. This technique is preferred because it is simple, increases operating room efficiency, and is reproducible. Biceps tenodesis is also associated with less muscle cramping, loss of supination strength, and cosmetic deformity. The use of an all-suture anchor allows the drilling of a much smaller hole in the humerus, which is associated with a decreased risk of postoperative fractures. In a study comparing methods of pectoralis major tendon repair, retears were only observed along the tendon-suture interface, highlighting the importance of suture construction as a limiting factor in postoperative outcomes.

Although tenotomy and tenodesis are both viable options for treating pathologies relating to the LHB tendon, the senior author (XXX) prefers a mini-open subpectoral biceps tenodesis. Tenodesis is especially beneficial for higher-activity patients who may be impaired by cramping and loss of elbow supination strength, as well as patients who are opposed to a Popeye deformity. Although the rehabilitation period for biceps tenodesis is longer to ensure maintained fixation of the biceps, it helps maintain the length-tension relation of the LHB tendon. In addition, the literature indicates that the subpectoral approach prevents over-tensioning of the biceps, which augments healing and prevents the tendon from migrating once attached.

humeral fractures during biceps tenodesis with interference screw fixation, which can be avoided through reducing the drill size in the humerus. In addition, a recent study has shown that biceps tenodesis with interference screw fixation had significantly reduced maximum torque and rotation failure, putting overhead throwers at risk. Furthermore, unicortical drilling with the all-suture anchor protects the axillary nerve, which is at greater risk when using bicortical drilling. Finally, suture tape reduces the risk of slippage and other complications sometimes seen with smaller-bore sutures. Table 2 presents pearls and pitfalls, and Table 2 lists advantages and disadvantages.

In conclusion, this article presents a technique for a mini-open subpectoral biceps tenodesis using an onlay technique with an all-suture anchor preloaded with needles and suture tape. This technique allows proper tendon fixation while minimizing potential complications.

14. Green JM, Getelman MH, Snyder SJ, Burns JP. All-arthroscopic suprapectoral versus open subpectoral tenodesis of the long head of the biceps brachii without the use of interference screws. *Arthroscopy* 2017;33:19-25.
Video 1. After standard diagnostic arthroscopy and treatment of concomitant pathology, an arthroscopic basket is introduced from the anterior portal while viewing through the posterior portal, and the long head of the biceps is incised at its attachment to the superior labrum using a basket (0-10 seconds). To perform the tenodesis portion of the procedure, the head of the bed is reclined an additional 20° to 30° (11-40 seconds). The arm is slightly supinated and abducted. A marking pen is used to mark the longitudinal incision just lateral to the axillary crease, and local anesthesia is administered to the incision site. A 3-cm longitudinal incision is made just beneath the inferior border of the pectoralis major and just medial to the anterior-medial border of the deltoid but lateral to the axillary crease (41-42 seconds). The subcutaneous tissue and fascial layer are exposed using Metzenbaum scissors, and the fascia is entered inferior to the pectoralis major and lateral to the short head of the biceps (43-46 seconds). A subpectoral plane is established in the direction of the humerus via blunt finger dissection, and the LHB tendon can be palpated in the bicipital groove adjacent to the pectoralis major tendon edge (47-58 seconds). A pointed Hohmann retractor is placed under the junction of the pectoralis major and anterior border of the deltoid (59 seconds to 1 minute 6 seconds). A Chandler retractor is placed on the medial aspect of the humerus with minimal tension (1 minutes 7 seconds to 1 minutes 11 seconds). The biceps is seen medial to the pectoralis major insertion and is retrieved using a finger or curved hemostat (1 minutes 12 seconds to 1 minutes 21 seconds). An electrocautery device is used with suction to create a landing zone near where the bicipital groove would be as it continues distally (1 minutes 22 seconds to 1 minutes 42 seconds). A bone cutter is used to excoriate the landing-zone surface (1 minutes 43 seconds to 1 minutes 50 seconds). The anchor is double loaded with two 1.3-mm suture tapes, with swedged-on needles on the opposite end (1 minutes 51 seconds to 2 minutes 3 seconds). The inserter is serrated at its tip. The drill guide can be used to further excoriate the landing zone (2 minutes 4 seconds to 2 minutes 27 seconds). The drill guide is slotted to allow for the use of swedged-on needles attached to the anchor. The drill guide is placed in the proximal bicipital groove, and a 1.9-mm hole is drilled (2 minutes 28 seconds to 2 minutes 32 seconds). While the position of the drill guide is maintained, a double-loaded all-suture anchor (Biceps FiberTak) is carefully impacted into the drill hole (2 minutes 33 seconds to 2 minutes 48 seconds). The slot on the guide allows for the use of swedged-on needles loaded with 1.3-mm suture tapes (2 minutes 49 seconds to 3 minutes 2 seconds). Two needles are cut off, and 1 suture from each pair is passed through the LHB tendon with running, reinforced sutures over a 2-cm length of the tendon (3 minutes 3 seconds to 3 minutes 41 seconds). Care is taken to re-establish normal tendon tension. The opposite ends of the paired sutures that were not passed are then used to tension and position the biceps tendon onto the humerus (3 minutes 42 seconds to 4 minutes). The sutures are tied sequentially to secure the tendon to bone (4 minutes 1 seconds to 4 minutes 11 seconds). The remaining LHB length and suture are excised, and the wound is copiously irrigated (4 minutes 12 seconds to 4 minutes 17 seconds). The wound is closed in a standard staged subcutaneous and subcuticular fashion using Monocryl suture and Dermabond (4 minutes 18 seconds to 4 minutes 20 seconds).
